## Photons and charges from colloidal doped semiconductor quantum dots

Tian Qiao,<sup>a</sup> David Parobek<sup>a</sup> and Dong Hee Son<sup>ib</sup>  <sup>★ab</sup>

The utility of colloidal semiconductor quantum dots as a source of photons and charge carriers for photonic and photovoltaic applications has created a large field of research focused on tailoring and broadening their functionality beyond what an exciton can provide. One approach towards expanding the range of characteristics of photons and charge carriers from quantum dots is through doping impurity ions (e.g.  $\text{Mn}^{2+}$ ,  $\text{Cu}^+$ , and  $\text{Yb}^{3+}$ ) in the host quantum dots. In addition to the progress in synthesis enabling fine control of the structure of the doped quantum dots, a mechanistic understanding of the underlying processes correlated with the structure has been crucial in revealing the full potential of the doped quantum dots as the source of photons and charge carriers. In this review, we discuss the recent progress made in gaining microscopic understanding of the photophysical pathways that give rise to unique dopant-related luminescence and the generation of energetic hot electrons *via* exciton-to-hot electron upconversion.

### 1. Introduction

The primary function of colloidal semiconductor quantum dots (QDs) in most of their applications is as a source of photons<sup>1–3</sup> or charge carriers.<sup>4–6</sup> Therefore, much effort was put into the research on controlling the characteristics of photons and charge carriers and improving the efficiency of generating them. For instance, the capability to control the wavelength, polarization and even the direction of photon emission of photons in an individual QD and an ensemble of QDs was sought in addition to

seeking a higher emission quantum yield when using them as the source of photons. As the source of charge carriers, producing and extracting electrons and holes with sufficient energy to perform electrochemical or electrical work with maximum efficiency is the main interest. In addition to varying the material itself, several other strategies have been used to achieve these, including quantum confinement,<sup>7–9</sup> anisotropic morphology,<sup>10–12</sup> surface modification<sup>13–15</sup> and heterostructure formation.<sup>16,17</sup>

Doping of QDs with certain metal ions has been explored extensively to expand the range of characteristics of photons and charge carriers beyond what can be achieved by changing the host nanocrystal structure and interfacial ligand chemistry.<sup>18–20</sup> For instance, isoelectronic doping of  $\text{Mn}^{2+}$  ions to replace the divalent metal ions in binary and ternary QDs resulted in sensitized photoluminescence originating from the ligand field transition

Tian Qiao

Tian Qiao obtained her BS from Zhejiang University, China. She is currently a PhD student in Prof. Dong Hee Son's group at Texas A&M University. Her research topic is the synthesis of strongly quantum confined perovskite nanocrystals and Mn-doping in these nanocrystals, and the spectroscopic characterization of an exciton and its coupling with a magnetic dopant.

David Parobek

David Parobek obtained his BS from the University of Pittsburgh. He is currently a PhD student in Prof. Dong Hee Son's group at Texas A&M University. His research topic is the transition metal doping of II–VI and perovskite nanostructures for hot electron-induced photocatalysis.

of  $\text{Mn}^{2+}$  in addition to exciton luminescence.<sup>21–24</sup> Doping of other metal ions such as  $\text{Cu}^{+19}$  and  $\text{Ag}^{+25,26}$  was also shown to introduce new photon emission pathways or alter the competition between the radiative and nonradiative recombination of excitons in the host QDs. Doping of  $\text{Mn}^{2+}$  ions has been recently shown to open new pathways that can produce energetic hot electrons *via* an exciton-to-hot electron upconversion process, enabling hot electron-induced photochemistry.<sup>27–29</sup> Some reports also suggested the possibility of Mn being an acceptor and donor of electrons in Mn-doped QDs, relaying the electron between the conduction band and its final destination.<sup>30</sup>

In this article, we will discuss the progress made in controlling the characteristics of photons and charge carriers produced in QDs *via* doping of cations with an emphasis on highlighting the developments in recent years. We will use the word colloidal QDs throughout this article in a broad and relaxed sense to represent semiconductor nanocrystals in general including not only the quantum confined 0-dimensional nanocrystals but also those with a very weak confinement effect. This article has two main sections discussing the control of the properties of photons and charge carriers by doping. Section 2 discusses non-exciton luminescence resulting from doping of the QDs *via* different mechanisms that depend on the identity of the dopant ions. Section 3 discusses the mechanism of producing hot electrons in Mn-doped QDs *via* a biphotonic exciton-to-hot electron upconversion process and the detection of hot electrons. The last part of Section 3 makes comments on the potential function of the Mn dopant as an electron acceptor and donor that has been suggested in the literature as the origin of the enhanced photovoltaic performance in QD-sensitized solar cells.

## 2. Photons from doped quantum dots

In this section, we will discuss the luminescence in several metal ion-doped semiconductor quantum dots (QDs), where the new radiative photophysical pathways introduced by the dopant produce new luminescence in addition to the exciton luminescence of the host QDs. While doping can also modify

the exciton luminescence of the host, for instance by creating a strong effective magnetic field under an external field,<sup>31</sup> the present review will focus on the new luminescence not originating from the exciton. Here, we will introduce QDs doped with three different prototypical dopants that emit photons through the following three distinct photophysical pathways that have been attracting much attention: dopant sensitization, recombination involving charge carriers localized on the dopant, and quantum cutting. When the QDs are doped with more than one type of dopant, the competition among different photon emitting pathways creates more diverse luminescence.<sup>32</sup>

### 2.1 Sensitization of dopants

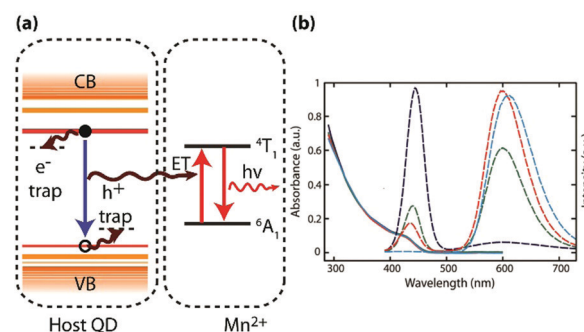

Mn-Doped QDs are among the most comprehensively studied doped QDs for their strong sensitized luminescence that arises from the ligand field transition of  $\text{Mn}^{2+}$  ions. Due to its relatively high luminescence quantum yield and large Stokes shift compared to the exciton luminescence, Mn luminescence has been extensively utilized in various applications including light emitting devices, bioimaging and solar concentrators.<sup>18,33–37</sup>

Intense sensitized Mn luminescence occurs *via* efficient energy transfer from the exciton to  $\text{Mn}^{2+}$  ions when the bandgap of the host QDs is sufficiently large to drive net unidirectional energy transfer from the exciton to the dopant as depicted in Fig. 1a. Because the energy of the ligand field transition is determined by the strength of the ligand field dictated by the coordination structure around  $\text{Mn}^{2+}$  ions, Mn luminescence energy is not as sensitive to the variation of the chemical identity of the host QD and its size and morphology as the exciton luminescence.<sup>38</sup> Therefore, most of the Mn-doped QDs exhibit luminescence of a similar color centered around 600 nm with relatively small variation (a few tens of nm) of the peak wavelength as shown in Fig. 1b. The variation of the energy and the lifetime of Mn luminescence in different Mn-doped QDs reflects the difference in the strength of the ligand field, spin-orbit coupling and inter-dopant exchange interactions.<sup>39</sup> So far, Mn doping in QDs has been reported in various binary and ternary systems as listed in Table 1, all of which exhibit orange-colored Mn luminescence

II–VI semiconductors	ZnO, <sup>40</sup> ZnS, <sup>41–44</sup> ZnSe, <sup>45–48</sup> CdS, <sup>42,48,49</sup> CdSe, <sup>31,50–54</sup> CdTe, <sup>48</sup> ZnCdS, <sup>55</sup> CdSeTe, <sup>56,57</sup>
Lead halide perovskites	CdS/ZnS, <sup>58–61</sup> ZnSe/CdSe/ZnSe, <sup>62</sup> CdSSe/ZnS, <sup>63</sup> ZnSe/ZnCdSe, <sup>64</sup> ZnSe/ZnS/CdS/ZnS, <sup>65</sup> CdS/ZnSe/ZnS <sup>66</sup>
Other semiconductors	CsPbCl <sub>3</sub> , <sup>67–73</sup> CsPb(Cl/Br) <sub>3</sub> , <sup>67,74–76</sup> CsPbBr <sub>3</sub> , <sup>73,77,78</sup> CsPbI <sub>3</sub> , <sup>79,80</sup> CH <sub>3</sub> NH <sub>3</sub> PbCl <sub>3</sub> , <sup>81</sup> PbSe, <sup>82</sup> InAs, <sup>83</sup> Ag–In–Zn–S, <sup>84</sup> Zn–Cu–In–S, <sup>85</sup> Zn–In–S <sup>86</sup> InP/ZnS, <sup>87</sup> Zn–Cu–In–S/ZnS, <sup>88</sup> Zn–In–S/ZnS <sup>89</sup>

when exciton-Mn energy transfer is allowed. Earlier synthetic efforts were focused on doping binary II–VI semiconductor QDs while the range of host QDs is expanding to ternary systems including CuInS<sub>2</sub> and lead halide perovskite QDs.

The quantum yield (QY) of Mn luminescence can be very high (~90%) when the appropriate host QD and doping concentration are chosen, indicating the efficient energy transfer favorably competing with other processes.<sup>60</sup> As in the case of undoped QDs, trapping of electrons or (and) holes is the major pathway that depletes the exciton population nonradiatively (Fig. 1a), although the trapped charge carriers can exhibit lower-energy trap emission.<sup>90–92</sup> The type of interaction that mediates the exciton-Mn energy transfer is the exchange interaction between excitons and *d* electrons of Mn<sup>2+</sup> ions, since the dipole-coupled energy transfer is inefficient due to the weak transitions between the ground state and the manifold excited ligand field states of Mn<sup>2+</sup> ions in the lattice.<sup>93</sup> Since the strength of the exchange interaction depends on the wavefunction overlap between the donor and acceptor, the rate of energy transfer is strongly dependent on the relative location of the dopant within the host QD and doping concentration especially for the strongly quantum confined QDs.<sup>60</sup>

Earlier studies estimated the rate of exciton-Mn energy transfer from the radiative and nonradiative decay rates of exciton and luminescence quantum yields.<sup>94–97</sup> On the other hand, such an indirect approach can be inaccurate especially when the ensemble of doped QDs are kinetically heterogeneous, where the average luminescence lifetime and average luminescence QY are not compatible with the rate equations describing a kinetically homogeneous system. A more reliable exciton-Mn energy transfer rate was obtained from a direct time-resolved measurement employing pump-probe transient absorption spectroscopy.<sup>98</sup> Using this approach, the rate of exciton-Mn energy transfer in Mn-doped CdS/ZnS core/shell QDs was measured by analyzing the difference in the bleach recovery dynamics of exciton transitions in undoped and Mn-doped QDs of the same host structure as a function of the doping concentration and radial doping location within the QD.<sup>60</sup> This study showed that the energy transfer rate increases with increasing doping concentration for a given radial doping location from increasing overlap of the exciton wavefunction with the dopant (Fig. 2). Depending on the doping concentration and location, the energy transfer time in Mn-doped CdS/ZnS QDs varied in the range of 4–80 ps. In this system, hole trapping that was identified as the main nonradiative competing channel occurred on a 50–100 ps time scale. The rapid exciton-Mn energy transfer compared to the exciton recombination and charge carrier trapping combined with inefficient nonradiative decay of the excited ligand field state of Mn<sup>2+</sup> ions is the reason why the Mn luminescence QY in Mn-doped QDs can be higher than the exciton

Fig. 2 Doping location and concentration dependent energy transfer rate constant of Mn-doped CdS/ZnS QDs. For a given doping concentration, energy transfer rate increases as Mn<sup>2+</sup> ions doped closer to the core. Energy transfer rate increases linearly to the doping concentration at a given radial doping location.  $\langle n_{\text{Mn}} \rangle$  is the average number of Mn<sup>2+</sup> ions doped in each QD. luminescence QY in undoped QDs. In the case of Mn-doped lead halide perovskite QDs that have been successfully synthesized in recent years, the exciton-Mn energy transfer rate was measured in Mn-doped CsPbCl<sub>3</sub> QDs *via* pump-probe transient absorption measurements.<sup>99</sup> The energy transfer rate in Mn-doped CsPbCl<sub>3</sub> QDs was somewhat slower than that in Mn-doped CdS/ZnS QDs, although a more accurate comparison between the two systems of the same QD size and dopant distribution within the QD has yet to be made. At a doping concentration of 0.4%, Mn-doped CsPbCl<sub>3</sub> NCs exhibited an energy transfer time of 380 ps, which is 2–5 times slower than that of Mn-doped CdS/ZnS QDs of comparable doping structure.<sup>99</sup>

It is worth mentioning that the trapping of the electron or hole that usually inhibits exciton-Mn energy transfer can in some cases still enable the energy transfer from the ‘trapped exciton’ state to Mn<sup>2+</sup> ions depending on the nature of the charge carrier trap. For example, introducing hole-trapping organic thiols as surface-binding ligands to Mn-doped CdS/ZnS QDs has been shown to increase the Mn luminescence intensity despite the fact that the same thiol ligand results in the quenching of exciton PL in undoped QDs *via* hole trapping.<sup>100</sup> This indicates that certain trapped excitons can be recovered as the sensitized Mn luminescence, although the energy transfer rate from the trapped exciton is significantly slower than the rate of ‘normal’ exciton-Mn energy transfer. The partial involvement of trapped excitons in the energy transfer has also been observed in CdS/ZnS QDs codoped with Mn<sup>2+</sup> and Ag<sup>+</sup>, where doping of Ag<sup>+</sup> can create the trapped exciton.<sup>26</sup>

As the bandgap of the host QDs becomes closer to the energy of the Mn ligand field transition involved in the energy transfer, the initial net unidirectional energy transfer begins to experience

back energy transfer from the dopant to the host QD. In this case, the relative intensity of the exciton and Mn luminescence varies depending on the donor-acceptor energy difference and temperature. The feeding from the long-lived emitting state of  $\text{Mn}^{2+}$  ( $^4\text{T}_1$ ) back to the host to populate the exciton state also results in a net elongation of the decay time of the exciton luminescence.<sup>101</sup> The robust dependence of the ratio of exciton and Mn luminescence intensities on the temperature, which is determined by the thermal equilibrium between the two states, has also been proposed for luminescence-based temperature sensing.<sup>64,102,103</sup>

As mentioned briefly earlier in this section, the spectral characteristics of Mn luminescence can be varied within a relatively narrow range by modifying the strength and structure of the ligand field or the extent of inter-dopant exchange coupling. For a given coordinating anion around  $\text{Mn}^{2+}$ , hydrostatic pressure or local lattice strain resulting from the lattice mismatch at the heterointerface alters the Mn luminescence energy by changing the ligand field strength.<sup>61,104</sup> With increasing pressure, Mn luminescence energy decreased.<sup>104</sup> In addition, the signature of softening the local vibrational mode coupled to the Mn ligand field transition is also observed when dopants are located close to the core/shell interface that imposes anisotropic lattice strain in Mn-doped CdS/ZnS QDs.<sup>105</sup> When the  $\text{Mn}^{2+}$  ions experience a stronger lattice strain, the spectral linewidth of Mn luminescence exhibits higher sensitivity to the temperature, which is explained by the lower frequency of the local vibrational mode coupled to the Mn ligand field transition compared to the bulk phonon of the host lattice. With increasing Mn-doping concentration, inter-dopant antiferromagnetic coupling becomes more significant resulting in the shortening of Mn luminescence lifetime.<sup>45,106</sup>

The advantage of Mn-doped QDs as the source of photons in various applications compared to undoped QDs comes from the large Stokes shift of dopant emission and multi-color emission whose intensity ratio can be used as a sensing modality. For example, the absence of self-absorption of Mn luminescence is ideal for the application of Mn-doped QDs as a solar down-converter and concentrator with low loss.<sup>107,108</sup> The sensitivity of the relative ratio of exciton and Mn emission to the chemical environment or temperature was utilized for chemical or temperature sensing.<sup>65</sup>

## 2.2 Recombination of charge carrier localized on dopants

Another avenue producing new luminescence in doped QDs is by introducing dopants that function as a charge carrier recombination center, where one of the charge carriers localized on or near the dopant radiatively recombines with the remaining charge carrier. Among the doped QDs that can exhibit luminescence *via* dopant-centered charge carrier recombination, Cu-doped II-VI QDs were the most extensively studied. Dopants that can produce luminescence *via* a similar mechanism include  $\text{Ag}^+$ ,  $\text{Cr}^{3+}$  and  $\text{Ni}^{2+}$ , while they have not been explored as extensively as the Cu dopant.<sup>20</sup> In contrast to Mn luminescence, the energy of Cu luminescence varies widely depending on the host QDs, *e.g.*, 3 eV in Cu-doped ZnS QDs and 0.9 eV in  $\text{Cu}_2\text{ZnSn}(\text{S}_{1-x}\text{Se}_x)_4$  QDs.<sup>109,110</sup> The Cu

luminescence decays on a  $\mu\text{s}$  time scale, because it involves the recombination of the localized charge carrier exhibiting much lower oscillator strength than the delocalized exciton.<sup>19</sup>

Earlier literature discussing the luminescence from Cu-doped QDs had two different views on the oxidation state of the dopant between  $\text{Cu}^{+111-114}$  and  $\text{Cu}^{2+}$ ,<sup>115-117</sup> which fueled many detailed studies to identify the oxidation state of the dopant. Various optical,<sup>114,118</sup> electron spin resonance,<sup>119,120</sup> X-ray absorption spectroscopic<sup>112,121-123</sup> and computational studies<sup>124</sup> were performed to clarify this issue. While we will not cover the full scope of the recent progress in this issue here, which are discussed in detail in a recent review,<sup>19</sup> we briefly highlight the key arguments supporting each view.

Studies by Gamelin and coworkers described the Cu luminescence as coming from QDs doped with  $\text{Cu}^+$ , where the rapid localization of the hole by  $\text{Cu}^+$  after the photoexcitation of the exciton results in the radiative recombination of the localized hole with the remaining electron<sup>114</sup> (Fig. 3a). In this picture, the initial hole localization on  $\text{Cu}^+$  produces a  $\text{Cu}^{2+}$  like state, which returns to  $\text{Cu}^+$  through the recombination with the electron giving rise to Cu luminescence.<sup>114</sup> The authors supported the  $\text{Cu}^+$  state of the dopant in Cu-doped QDs by comparing the calculated absorption spectra of  $\text{Cu}^+$ - and  $\text{Cu}^{2+}$ -doped CdSe clusters ( $\text{Cu}^+:\text{Cd}_{33}\text{Se}_{34}$  and  $\text{Cu}^{2+}:\text{Cd}_{33}\text{Se}_{34}$ ).<sup>124</sup> In their work, they argued that only  $\text{Cu}^{2+}:\text{Cd}_{33}\text{Se}_{34}$  exhibits a distinct valence band-to-metal electron transfer transition extending into the near infrared (NIR) region at  $<1$  eV, which has been experimentally observed in bulk ZnS doped with  $\text{Cu}^{2+}$  but not in Cu-doped ZnS QDs. The authors also reported the observation of valence band-to-metal electron transfer in the transient absorption studies of Cu-doped CdSe/CdS core/shell QDs as a weak photoinduced absorption, fortifying the mechanism of forming a  $\text{Cu}^{2+}$  state through hole localization at  $\text{Cu}^+$  after photoexcitation.<sup>118</sup> In addition, an absorption peak at 2.7 eV in the calculated absorption spectrum of  $\text{Cu}^+:\text{Cd}_{33}\text{Se}_{34}$ , attributed to the transition of the electron in  $\text{Cu}^+$  to the conduction band of the host, was observed experimentally below the band to band transition in Cu-doped CdSe QDs.<sup>114</sup> These results were taken as a strong support for the argument that the oxidation state is  $\text{Cu}^+$  in Cu-doped QDs.

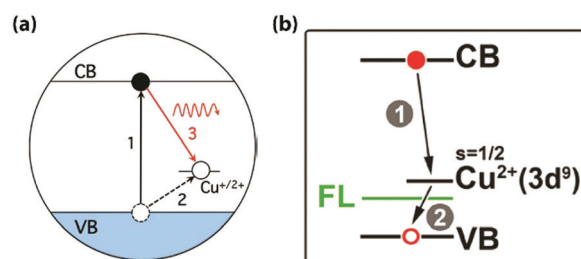

Fig. 3 (a) Copper dopant exists in the QDs as  $\text{Cu}^+$  that rapidly localizes a hole after the photoexcitation. The localized hole recombines with the electron to emit a photon. Reproduced with permission from ref. 114. Copyright American Chemical Society (2015). (b) Copper dopant exists in the QDs as  $\text{Cu}^{2+}$  that acts as a permanent hole, which recombines with the electron to emit a photon. Reproduced with permission from ref. 125. Copyright American Chemical Society (2011).

On the other hand, studies by Klimov and coworkers suggested that the dopant exists as  $\text{Cu}^{2+}$  in the QDs and acts as a permanent hole in the QD that recombines with the electron in the conduction band to produce the dopant luminescence and  $\text{Cu}^+$  (Fig. 3b).<sup>125</sup> In their study, they reported magnetic circular dichroism (MCD) data of Cu-doped ZnSe/CdSe QDs showing an enhanced Zeeman splitting of 2.5 meV indicative of magnetic activity associated with  $\text{Cu}^{2+}$  with a  $d^9$  as opposed to  $\text{Cu}^+$  with a  $d^{10}$  configuration of d electrons. On the other hand, this has been disputed by another study that reported the absence of electron paramagnetic resonance (EPR) signals and MCD from Cu-doped CdSe, InP and  $\text{CuInS}_2$  QDs, leaving room for further clarification.<sup>114</sup> The authors also observed an increase of Cu luminescence intensity when dodecanethiol was introduced onto the Cu-doped ZnSe/CdSe QD surface, which acted as a hole trap that removed the hole produced in the valence band of the host after the photoexcitation.<sup>125</sup> This observation was interpreted as the result of the competition between the permanent hole on  $\text{Cu}^{2+}$  and the photogenerated hole in the valence band in the recombination with the electron in the conduction band, supporting the  $\text{Cu}^{2+}$  dopant state. However, the absence of a channel regenerating the  $\text{Cu}^{2+}$  state from  $\text{Cu}^+$  after charge carrier recombination that was required to sustain Cu luminescence under continued photoexcitation was pointed out as a weakness of the  $\text{Cu}^{2+}$  scenario.<sup>114</sup>

### 2.3 Downconversion by quantum cutting

Downconversion *via* quantum cutting has also been studied recently in lanthanide doped nanocrystals.<sup>126–129</sup> Quantum cutting that produces two lower energy photons from one high-energy photon has been more frequently observed in insulating host materials doped with one or more types of lanthanide dopant ions that form a donor and acceptor pair.<sup>130,131</sup> Often, the ‘cutting’ of one high-energy photon into two low-energy photons occurs by transferring the energy from one donor ion to two acceptor ions, although the exact pathways of energy transfer varies depending on the identity of the lanthanide ions involved as illustrated in Fig. 4a.<sup>132</sup> For instance, in a  $\text{Tb}^{3+}$ – $\text{Yb}^{3+}$  couple,  $\text{Tb}^{3+}$  is the donor and two  $\text{Yb}^{3+}$  ions are the acceptors represented by case II of the scheme in Fig. 4a.<sup>130</sup>

Recently, several groups reported the enhancement of quantum cutting efficiency by taking advantage of the sensitization by organic dyes or by using semiconductor QDs as the host matrix absorbing the high-energy photons efficiently.<sup>126–129,133</sup> As a semiconductor host that can exhibit the enhanced quantum cutting, lead halide perovskite QDs have attracted much attention in recent years with the successful synthesis of lanthanide doped cesium lead halide ( $\text{CsPbX}_3$ ) QDs. In the case of Yb-doped  $\text{CsPbCl}_3$  QDs, downconversion of the visible light to near infrared (NIR) photons was achieved with an efficiency of up to 170%.<sup>127</sup> In this case, the exciton initially excited in  $\text{CsPbCl}_3$  QDs was considered to rapidly localize at the defects introduced by heterovalent doping as depicted in Fig. 4b. The subsequent energy transfer from the trapped exciton to the two adjacent  $\text{Yb}^{3+}$  ions produce two NIR photons at  $\sim 1.26$  eV.

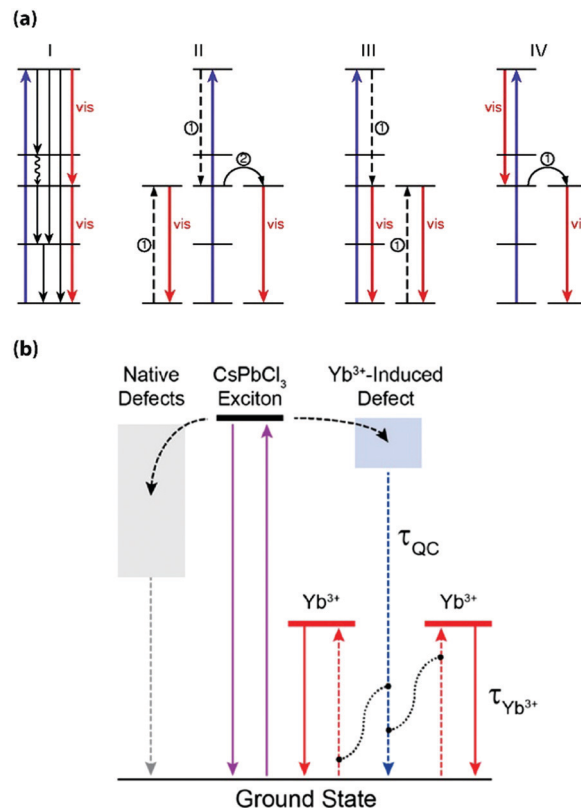

Fig. 4 (a) Energy level diagram showing the different pathways of quantum cutting involving lanthanide ions. Blue arrows indicate photoexcitation of lanthanide ions and red arrows indicate the emission of a downconverted photon. In case I, a single excited ion emits two photons sequentially. Quantum cutting can also occur *via* single-step (III and IV) or two-step (II) energy transfer to another lanthanide ion. Reproduced with permission from ref. 132. The  $\text{Yb}^{3+}$ -induced defect state localizes the exciton and a pair of  $\text{Yb}^{3+}$  ions are sensitized simultaneously by the trapped exciton. Reproduced with permission from ref. 127. Copyright American Chemical Society (2018).

## 3. Charge carriers from Mn-doped quantum dots

While the role of dopants in tuning the spectral characteristics of the luminescence has been the main interest in many studies on doped QDs as discussed in the previous section, interest in altering the properties of the photoexcited charge carriers is also growing. Here, we will first discuss hot electron generation in Mn-doped QDs that takes advantage of the long-lived excited Mn ligand field state enabling the sequential ‘upconversion’ of two excitons into a hot electron hole pair at low excitation intensities. In this process, the sensitized excited ligand field state of  $\text{Mn}^{2+}$  functions as a long-lived energy reservoir for the sequential resonant two-photon process. This process can be compared to the photon upconversion observed in many lanthanide doped nanocrystals except that a higher energy charge carrier is obtained instead of a higher energy photon.<sup>134</sup> In the last part of this section, we will discuss the feasibility of Mn dopants functioning as the electron storage and relay enhancing

the charge collection efficiency in photovoltaic device platforms that has been suggested in some literature studies.<sup>30</sup>

### 3.1 Hot electrons from doped quantum dots

Mn-Doped QDs have received particular attention as the source of hot electrons from semiconductor QDs, since the long-lived ligand field state of Mn functions as the energy reservoir playing a critical role as the intermediate state in producing hot electrons *via* the sequential two photon process.<sup>135,136</sup> Generation of hot electrons in Mn-doped QDs reported so far used II–VI QDs as the host while new platforms such as lead halide perovskite QDs are being pursued as a new host material. Because of their large excess kinetic energy, hot electrons exhibit superior electron transfer capability compared to the lower energy bandedge electrons. For this reason, hot electrons are actively pursued for various photophysical and photochemical applications such as in photovoltaics<sup>27</sup> and photocatalysis.<sup>63</sup>

The mechanisms of producing hot electrons in Mn-doped QDs were proposed early in this decade and the experimental detection of hot electrons as the photocurrent in electrochemical cells, photodiode platforms and also as photoelectron emission followed soon.<sup>27–29,135,136</sup> Fig. 5 shows the two proposed photophysical pathways that can generate highly energetic hot electrons.<sup>135,136</sup> One is two consecutive exciton-Mn energy transfer to the same  $\text{Mn}^{2+}$  as illustrated in Fig. 5a, which was proposed by the authors' group.<sup>136</sup> This produces highly excited  $\text{Mn}^{2+}$  ions that can give up the electron to the conduction band of the host with significant excess kinetic energy and recover the  $\text{Mn}^{2+}$  oxidation state by creating a localized hole near the dopant. This mechanism was initially proposed from the observation of the decrease of the intensity of Mn luminescence from the  ${}^4\text{T}_1 \rightarrow {}^6\text{A}_1$  transition with increasing excitation rate due to the loss of the emitting  ${}^4\text{T}_1$  population in Mn-doped CdS/ZnS QDs. Another proposed pathway for the generation of hot electrons is the exciton-Mn energy transfer followed by Auger energy transfer from the  ${}^4\text{T}_1$  state of  $\text{Mn}^{2+}$  to the exciton excited by the second photon absorption as illustrated in Fig. 5b.<sup>137</sup> In this case, the  ${}^4\text{T}_1$  state of the  $\text{Mn}^{2+}$  ion can transfer energy to either an electron or a hole. In an earlier work reported by Gamelin and coworkers,

they observed the quenching of Mn luminescence upon the electrochemical injection of an electron into the conduction band of the host, which was explained by the Auger deexcitation of the  ${}^4\text{T}_1$  state of the  $\text{Mn}^{2+}$  ion by the injected electron.<sup>137</sup> If the Auger deexcitation of the  ${}^4\text{T}_1$  state of the  $\text{Mn}^{2+}$  ion involves primarily the electron of the photoexcited electron rather than holes, the net result is the generation of a hot electron in the conduction band and a delocalized hole in the valence band.

While it is not straightforward to tell which particular mechanism dominates under a given condition, both pathways produce hot electrons with excess kinetic energy in the conduction band. On the other hand, the energy level of hot electrons and its dependence on the host bandedge level are different in the two cases. Since the hot electrons from pathway (b) are produced by transferring the energy from the  ${}^4\text{T}_1$  state of  $\text{Mn}^{2+}$  to the electrons in the conduction band, the energy of hot electrons can be varied by tuning the host bandedge, whereas pathway (a) will produce hot electrons whose energy is insensitive to the host bandedge level. One important aspect of hot electron generation in Mn-doped QDs common to both pathways in Fig. 5 is the extremely long lifetime of the  ${}^4\text{T}_1$  state of  $\text{Mn}^{2+}$  that serves as the intermediate state for the sequential two-step process. Despite the fact that hot electron generation is biphotonic, it can occur at a very low excitation intensity thanks to the long intermediate state lifetime. For  $>5$  ms lifetime of the  ${}^4\text{T}_1$  state of  $\text{Mn}^{2+}$  doped in CdS/ZnS QDs, excitation intensities equivalent to the concentrated solar radiation were sufficient to produce hot electrons *via* the biphotonic upconversion process.<sup>63</sup>

The direct experimental verification of the generation of hot electrons was made in several different platforms. In the authors' group, hot electron photocurrent was first measured in a photo-electrochemical cell platform shown in Fig. 6a.<sup>28</sup> The anode is constructed by depositing CdS/ZnS QDs on an ITO substrate that has an  $\text{Al}_2\text{O}_3$  overlayer of varying thickness on top of the ITO layer.  $\text{Al}_2\text{O}_3$  is an insulating layer that provides a high energy barrier for the electrons near the edge of the conduction band. Only hot electrons with sufficient excess energy can tunnel through this insulating barrier. When undoped CdS/ZnS QDs were deposited on the anode, no detectable photocurrent was observed. In contrast, anodes deposited with Mn-doped CdS/ZnS QDs exhibited photocurrent that increased superlinearly with excitation intensity, which was consistent with the biphotonic hot electron generation mechanism, as shown in Fig. 6b.

Another study from the authors' group that showed the generation of hot electrons more directly was performed using the CdS/ZnS QD-coated ITO substrate as the source of photoelectrons under vacuum.<sup>29</sup> Fig. 6c shows the setup that measured the current from the photoelectron emission of hot electrons. In this experiment, while the average energy of hot electrons produced in Mn-doped CdS/ZnS QDs is below the vacuum level, a subset of hot electrons that exceeds the ionization threshold at the high-energy tail of the energy spectrum are emitted as photoelectrons. The photoelectron current densities measured at 0 V bias between the ITO and copper electrodes are compared between Mn-doped and undoped CdS/ZnS QDs in Fig. 6d. As expected from the biphotonic

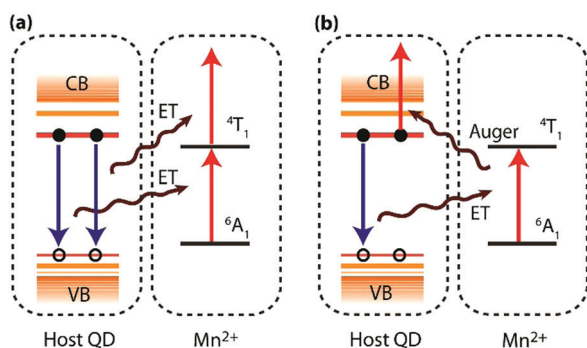

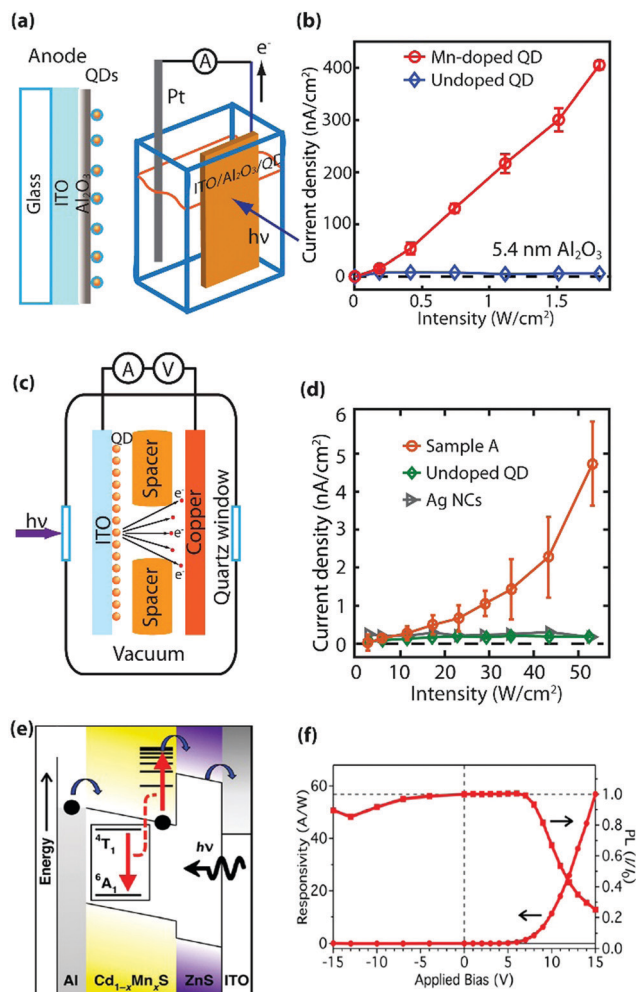

Fig. 5 Photophysical pathways that generate hot electrons in Mn-doped QDs. (a) Hot electrons are generated by consecutive exciton-to-Mn energy transfer. (b) Hot electrons are generated by exciton-to-Mn energy transfer followed by Auger type back energy transfer from  $\text{Mn}^{2+}$  to conduction band electrons.

upconversion process for the generation of hot electrons, only Mn-doped CdS/ZnS QDs exhibit the hot electron photoemission current that increases approximately quadratically with the excitation intensity. For comparison, a measurement using Ag nanocrystals capable of producing plasmonic hot electrons under the same excitation condition is also made. In contrast to Mn-doped CdS/ZnS QDs, the energy level of hot electrons from Ag nanocrystals is too low to produce a measurable photoemission current because the excess energy from the plasmon is used to promote the electron from below the Fermi level.

Detection of hot electrons in the photodiode platform was reported by Gamelin and coworkers.<sup>27</sup> Fig. 6e shows the energy

level structure of each component layer in the photodiode structure used to measure the hot electron photocurrent. In this photodiode structure, ZnS is the blocking layer that allows only the electrons with sufficient energy, *i.e.*, hot electrons, to generate the photocurrent. The photocurrent is observed only when the electron is injected to the layer of Mn-doped CdS QDs under sufficiently positive bias, as shown in Fig. 6f, so that Auger deexcitation of the  $^4T_1$  state of  $Mn^{2+}$  to the injected electron can produce hot electrons. Generation of hot electron photocurrent is also accompanied by a decrease of Mn luminescence as required by the mechanism of hot electron generation.

### 3.2 Possibility of Mn as the electron acceptor and donor

The possibility of  $Mn^{2+}$  ions in Mn-doped QDs to function as the acceptor and donor of 'electrons' has recently been discussed in the literature. Such a possibility has been suggested from the observation of the increased photocurrent in the photovoltaic devices fabricated with Mn-doped QDs compared to those fabricated with undoped QDs.<sup>138,139</sup> Mn dopant's possible electron relaying function has also been suggested to explain the slower recombination of the spatially separated charge carriers in the Mn-doped type-II core/shell quantum well structure compared to its undoped counterpart.<sup>57</sup> In these studies, the enhanced photocurrent or slower recombination of the charge carrier was attributed to the long-lived charge carriers, specifically electrons, residing in a state created by Mn doping. In a study by Kamat and coworkers, the authors explained the increase of photocurrent and photovoltage from Mn doping in QD-sensitized solar cells with the electron-accepting midgap state formed by Mn doping while not being specific about the nature of the midgap state.<sup>138</sup> Another study performed on Mn-doped CdSe QDs also reported the enhancement of photocurrent by Mn doping, indicating the involvement of some type of trap state that can hold the electron longer, therefore improving the charge carrier collection efficiency.<sup>139</sup> On the other hand, some of the later studies interpreted such enhanced photocurrent as a result of the long lifetime of photogenerated charge carriers that reduces the electron hole recombination, attributing the longevity of the carrier lifetime to the long lifetime of the  $^4T_1$  ligand field state.<sup>140</sup> However, such an interpretation is problematic since the  $^4T_1$  state is created by the transfer of the energy of the exciton (*i.e.*, both electron and hole pair) not just electrons to reduce the electron hole recombination. Some reports incorrectly portrayed the  $^4T_1$  ligand field state as the charge accepting level of the Mn dopant that resides within the bandgap of the host that relays the electron from the conduction band of the host QD to other nanocrystals such as  $TiO_2$  in the Mn-doped  $CuInS_2/CdS$  QD-sensitized solar cells.<sup>141</sup> In a study by Ghosh and coworkers, it was suggested that  $Mn^{2+}$  can be reduced to  $Mn^{1+}$  by capturing the electron from the conduction band of the host for a prolonged period and donating the electron back to the host, therefore performing the function of electron storage.<sup>57</sup> While doping of  $Mn^{2+}$  ions may potentially create a defect state near the dopant that can trap and detrapp the electrons with effective elongation of electron lifetime, more conclusive evidence for the involvement of the  $Mn^{2+}/Mn^{1+}$  redox process has yet to be acquired.

## 4. Conclusion and outlook

We discussed modification of the characteristics of photons and charge carriers in photoexcited colloidal QDs by introducing dopants in the QD lattice that open new pathways of energy or charge flow. Compared to the exciton luminescence of the host QDs, dopant luminescence covers a larger spectral range for a given host QD by utilizing various radiative decay pathways that depend on the specific dopant present in the host. While the interest in doped QDs has been focused on the spectral tunability of the luminescence, doped QDs are also a useful platform for exploring the coupling among electronic, lattice and spin degrees of freedom. Through the magnetism carried by the dopant or its ability to localize the charge, one could gain additional control of the properties of photons emitted, which will further expand the functionality of the doped QDs as the source of photons. Hot electrons from the doped QDs are also attracting attention for their capability to perform more efficient electron transfer overcoming a high and wide energy barrier. Photocatalytic reduction is an example where the hot electrons can be particularly useful. Compared to the plasmonic hot electrons produced in metal nanocrystals, hot electrons from Mn-doped QDs are more energetic by several eV because of the biphotonic upconversion process using the energy of two excitons. The high energy of hot electrons even capable of being above the vacuum level combined with the low required photoexcitation intensity for upconversion can open the door to practical utilization of energetic hot electrons for photochemical processes. The progress made in the control of the characteristics of photons and charges in doped QDs is the result of the combined efforts in developing the synthesis methodologies and in understanding the underlying principles at the microscopic level, which will continue to be crucial for future research in this field.
